

AI meets AD: Coining the future of early and accurate prediction of Alzheimer's Disease progression

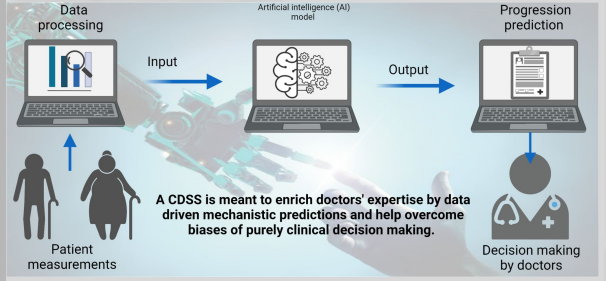

Students: Andrade Leon, R.; Bruton, O.; Jafri, S. / Supervisor: Prof. Dr. Andrea Hildebrandt

Background

Alzheimer's Disease (AD) is a **progressive** neurodegenerative disease known to severely impact cognitive functions. By the year 2050, 35% in developed countries and 21% of all individuals worldwide are predicted to be older than 60 years (United Nations, 2005).

The **progression strength of AD differs across individuals** and its prediction is challenging even for experienced clinicians. However, mechanistic (statistical) predictions were shown to outperform clinicians' predictions which are prone to biases, such as ignoring base rates, assigning non-optimal weights to features, and failure to properly assess covariation. Machine learning algorithms - when trained with sufficient data - might be more accurate in predicting the progression of AD.

Aim: Contrast different machine learning algorithms with respect to their prediction accuracy of AD progression. These algorithms might be implemented into **Clinical Decision Support Systems (CDSS)** to improve clinical recommendations.

Study design and input features

Alzheimer's Disease Neuroimaging Initiative (ADNI)
Longitudinal multicenter study
Aim: utilisation of various biomarkers/indicators for timely discovery of Alzheimer's disease
Participant age range: 55-90 from 57 sites (US & Canada)

Imaging data
-Longitudinal MRI
-measure/cumulative temporal lobe atrophy change scores over 6 months
-Baseline & longitudinal MRI ventricular volume (ml)
-Baseline MRI whole brain volume (ml)

Genetic data
-Polygenic hazard score
-Genetic risk variants associated with Alzheimer's disease
-APOE-ε4
-APOE-ε2

Clinical data
-Functional assessment questionnaire
-Neuropsychological Test Battery
-Baseline demographic data and family history

Biomarker data
-CSF biomarker Tau (pg/ml)
-Amyloid beta 42 result in plasma (pg/ml)
-Amyloid beta 40 result in plasma (pg/ml)
-Baseline Tauorurodeoxyacetic acid (M)

Central features of the analysed sample (N = 337):
Slow progression group: N = 142
Moderate progression group: N = 165
Fast progression = high risk group: N = 30
Mean age: 84 years
Gender (m/f): 58.5 % / 41.5%
Seven measurement timepoints

Results

Identifying AD progression classes

Latent class growth curve model with a linear and a quadratic slope

- Latent classes were allowed to vary in intercept, linear and quadratic slope
- The number of classes was identified in a stepwise manner, by comparing the log-likelihood of models with an additional class
- Adding a fourth class to the model did not substantially improve the model fit
- A three class solution revealed a slow progression, a moderate progression, and a fast progression (high risk) group

High risk = fast progression individuals turned out to be much less frequent in this sample → a **class imbalance problem** to be addressed when training machine learning models

Machine Learning methods applied

Naive Bayes classifier builds upon the Bayes' Theorem. It assumes the features to be mutually independent and outputs the highest probability for a given class.

Linear Discriminant Analysis maximizes the component axes for class separation in order to find the axes for best class separability.

Random Forest classifier is an ensemble algorithm, which creates a set of decision trees (each a bit different from the other) from a randomly selected subset of the training dataset, which then aggregates the votes from different decision trees to decide the final class of the test observation.

Support Vector Machines are based on the idea of finding a hyperplane that best divides a dataset into two or more classes depending on the input features.

All analyses were performed by means of the **mlr** package in the R Software for Statistical Computing.

Conclusions and future directions

Developing machine learning algorithms is a challenge in case of imbalanced data between the AD progression classes. Resampling techniques can be used to overcome this problem.

Naive Bayes and SVM evince higher accuracy in correctly classifying individuals in the original dataset. Predictive sensitivity for both the high and the moderate risk class appears to be best for Naive Bayes and SVM.

Due to their disproportionate relevance, imaging variables (e.g., baseline MRI whole brain volume), neuropsychological tests and certain biomarkers (e.g., baseline Amyloid-β 42) should be focussed on when predicting risk for fast progression of AD symptoms over time.

Further data is needed to test the robustness of the achieved predictions and to better overcome the class imbalance problem in the future.

Algorithmic predictions need experts' acceptance prior to designing a CDSS.
